**AQUIFER DESIGNATION FOR UIC:
PROTOTYPE STUDY IN SOUTHEASTERN NEW MEXICO**

INTRODUCTION

The New Mexico Oil Conservation Division (OCD), in conjunction with Lee Wilson and Associates, has performed a prototype study to implement the aquifer designation regulations which are proposed as part of the Federal Underground Injection Control program. Designation criteria require protection of aquifers which are currently used for drinking water or which have a total dissolved solids (TDS) content of less than 10,000 mg/l. However, aquifers may be exempted from designation if they are or will be used for mineral, oil or geothermal energy production, or if they cannot provide drinking water for reason of economics, technology or gross contamination.

In New Mexico, state regulations already require that ground water with a TDS less than 10,000 mg/l be protected against virtually all types of pollutant discharge. UIC goes beyond the State programs by requiring explicit identification and mapping of the areas to be protected. However, aquifers

protected under State regulations could be exempted from protection under UIC in areas of mineral, oil or geothermal energy production. Because the concept of designation or exemption is new, and standardized procedures are not available, the process of aquifer evaluation is potentially difficult, complex, and time-consuming; it may be expensive in terms of the commitment of resources for data gathering and interpretation. A prototype study is needed to develop procedures and evaluate the complexity and expense of the aquifer-designation process. The prototype reported here involved all steps in the process except for those related to a formal public hearing.

The project described here involved the mapping of aquifers in a 144-square-mile area near Artesia, in Eddy County (Figure 1). Characteristics of the area include the following:

1. Both artesian water and oil are produced from the same geologic unit, the San Andres Formation of Permian age. This situation is characteristic of much of southeastern New Mexico and implies that boundary-setting in aquifer designation must be precise.
2. Injection into the San Andres is practiced both for secondary recovery and brine disposal; thus the

potential for contamination is significant and the role of UIC designations as a protective tool becomes important.

3. Considerable information on the area has already been compiled by agencies or private companies (for example, water-level maps). Additional data can be readily obtained (for example, porosity values can be read from modern geophysical logs).

METHODS AND DATA

Geologic, hydrologic, and energy-resource data for the study area were gathered from published reports and the files of federal, state and local agencies concerned with water or energy resources. Information on salinity and porosity was developed in part from geophysical logs produced from new, deep gas wells which penetrated the Grayburg-San Andres interval. The Dual Laterlog and Compensated Neutron Log were utilized to determine resistivity of formation fluids and formation porosity. With proper borehole corrections, these logs provide an accurate assessment of fluid salinity. However, data are generally available only for deeper formations, since wells are required to be cased through formations known to contain potable water. The data were compiled into four tables (Tables

1 to 4), which include geohydrologic information, records of water wells, and records of oil, gas and injection wells (including geophysical data wells), and lithologic descriptions. The tables were then interpreted to produce maps basic to the aquifer designation process (see Figures 2 through 9); the maps present structural contours, potentiometric surfaces, the location of shallow oil and gas pools, and the location of information wells.

The maps and tables were used to develop Figure 10, a cross-section of the study area. This cross-section portrays most of the information needed to make aquifer designations. The section shows the location of fresh water, oil and gas pools, geologic boundaries, potentiometric surfaces of shallow and artesian aquifers, and representative wells. Figure 10 is used as the base for the various designation options considered in the Results section.

The geology of the study area (see Figures 2, 3 and 4) reflects its position as a backwater depositional zone in the Permian Reef complex of New Mexico and Texas. Dolomites predominate, with limestone increasing southeastward toward the reef, and redbeds and evaporites increasing north and west onto the shelf. In general, the Permian units dip toward the southeast and thicken in the same direction.

The principal aquifer and hydrocarbon-producing zones both occur within the San Andres Formation, which lies between the Grayburg Formation of the Artesia Group, and the Glorieta Sandstone. This formation is therefore the critical interval for UIC protection. Two separate porosity horizons are situated within the San Andres. The upper horizon is a high-porosity (20 per cent) interval which contains an artesian aquifer and some isolated hydrocarbon development. The artesian aquifer underlies most of the area. The Aquifer includes much of the Grayburg as well as the upper, porous zone of the San Andres. The water contains less than 3000 mg/l dissolved solids, except in the southeastern part of the map area where oil is produced from the lower Grayburg.

The lower horizon corresponds to the Slaughter dolomite zone, where locally developed porosity contains oil and gas, and total dissolved solids exceed 10,000 mg/l. A zone of low porosity apparently acts as a confining horizon, or permeability barrier, which separates the aquifer from the Slaughter zone and the oil pools.

Data on geohydrology and water quality in the area (see Tables 2 and 3, Figures 5, 6, 7) indicate that although fresh water is found to the base of the San Andres in some locations,

there is no water production below the artesian aquifer. (However, fresh water is found beneath the San Andres in the Roswell Basin outside the study area; see Gross et al., 1978).

In most locations, fresh water is not found in wells which penetrate below the artesian aquifer. However, resistivity data indicate that fresh water may extend to the base of the San Andres in some locations (Arrow A, Figure 10). In all such cases, geophysical logs indicate that the fresh water occurs in rocks with low porosity (averaging less than 7 percent), suggesting that the water is interstitial. No fresh-water yield is obtained from any well which penetrates below the artesian aquifer. Water in the Glorieta exceeds 10,000 mg/l in all geophysical data wells.

In units east of the Pecos River, water contains more dissolved solids than in corresponding units west of the river. Most fresh-water production comes from the Yates Formation, with dissolved solids values which can be as low as 1,000 mg/l, but are generally above 4,000 mg/l.

A shallow aquifer extends from the western portion of the prototype area to the Pecos River (Figures 4 and 5). The aquifer includes the valley alluvial fill and upper portion of the Seven Rivers Formation. Little information is available for the lower Seven Rivers and Queen Formation, below the shallow aquifer, since they serve only as a minor source of water within the basin.

Shallow hydrocarbon development occurs primarily in the eastward-dipping Slaughter zone within the San Andres Formation (see Table 3; Figures 8 and 10). Six million barrels of oil have been pumped from over 400 wells in 10 pools which occur in the prototype area. Production has depleted to non-profitable levels in most wells and underground injection is applied for enhanced recovery in the Atoka San Andres, Atoka Grayburg, and Red Lake pools (Figure 8). Salt-water disposal is active in two wells.

Subtle changes of strike and dip and effective porosity development within the Permian units control regional pinchouts of hydrocarbon production, and separate many pools produced within similar horizons. Absence of vertical permeability development within the San Andres protects the artesian aquifer against oil migration from lower depths. Hence, contamination

of the artesian aquifer by the underlying oil pool is unlikely. Local porosity along the Artesia Vacuum Arch within the Grayburg creates some oil production from facies above the Slaughter zone. Here, absence of vertical permeability development also protects the artesian aquifer. This trend continues east across the Pecos River in zones separated by permeability barriers. Most of these shallow pools have been depleted to production rates of less than one barrel per day per well.

Several points developed in the Methods section affect the four aquifer designation alternatives considered below. A considerable amount of fresh water which must be protected against contamination by underground injection is available in the study area. The shallow aquifers do not affect the designation process since they are underlain by the deeper artesian aquifer. Thus designation of the deeper aquifer will also protect the shallow aquifers. While oil production takes place as high as the top of the Grayburg, and fresh water is found to the base of the San Andres, no fresh-water production occurs below the artesian aquifer. There is a geologic basis in a large part of the study area for distinguishing between the upper porous horizon containing water and the lower porous horizon containing oil and gas.

RESULTS

Four alternatives were considered in the prototype study; three reflect a principle of designation (or exemption) contained in the UIC regulations, and the fourth is a combination containing the best overall approach.

Alternative 1. The entire stratigraphic interval to the base of the San Andres could be designated as an aquifer requiring UIC protection, with exemption for areas in which hydrocarbon production occurs.

Alternative 2. The interval could be designated as an aquifer only where total dissolved solids are less than 10,000 mg/l.

Alternative 3. The interval could be designated as an aquifer only where production of fresh water is likely to be economically or technically feasible.

Alternative 4. A combination of options 2 and 3 could be used. This alternative is the one recommended for the prototype area.

Each alternative must be judged in terms of: a) its effectiveness in protecting drinking water; and b) its administrative efficiency. Figures 11-15 display the various aquifer designations which would result from each alternative.

Alternative 1; Full Designation with Exemptions for Hydrocarbon Production

If the lower limit of the aquifer were designated as the base of the San Andres (see Figure 11), all known fresh water in the study area would be protected since TDS exceeds 10,000 mg/l throughout deeper horizons. Upper and lateral boundaries of active oil pools would then be used to exempt areas of hydrocarbon production. The heavy dashed line in Figure 11 illustrates how such a boundary would appear in cross-section.

This approach promises good protection of drinking water. The available evidence indicates that hydrocarbon production occurs within localized porosity zones (potential injection zones) which are unconnected to the artesian aquifer; further, fresh water has not been found beneath any oil pool. Therefore, wastes injected into areas exempted from designation would not be expected to commingle with fresh water in the protected aquifers. However, the approach would face severe

administrative problems. Boundaries must be redrawn each time an oil pool is extended or a new pool developed, requiring a lengthy and expensive public review and hearing process on each boundary change. Further, determination of the exact location of pools (especially the upper limit) is quite time-consuming.

Alternative 2: Use of TDS Boundary

Use of a line to define the lower limit of water containing less than 10,000 mg/l solids would, by UIC definition, provide protection to all potential drinking water (see Figure 12). The major drawback to using this method throughout the study area is that there are no water-quality analyses available from the lower part of the San Andres, nor from many higher units east of the Pecos River. Instead, the determination that fresh water occurs to the base of the San Andres Formation involves the use of resistivity data from deep geophysical data wells. There are relatively few geophysical data wells; hence the boundary can only be approximate and the depth to which UIC protection should extend is uncertain. East of the river the line is drawn across the top of oil pools because elsewhere in the area TDS values in and beneath beneath pools are always greater than 10,000 mg/l. Administration of a designation

based on approximate boundaries and uncertain depths would be difficult. In addition, evaluations of resistivity data from geophysical data wells is time-consuming and hence expensive. The approach may be the only one feasible in much of New Mexico, but in the prototype area a better procedure is available (see below).

Alternative 3: Boundary Based on Porosity

The fresh water which lies between the base of the artesian aquifer and the base of the San Andres appears to be interstitial, trapped in pore spaces with little or no permeability. It is doubtful that usable quantities of water could be obtained by wells which tap this horizon. Therefore, the base of the artesian aquifer itself could be used as a UIC boundary in the study area since it effectively limits the depth at which fresh water resources are available (see Figure 13). The boundary is readily drawn based on the extensive well records available in the area. In practice it is preferable to place the base of the protected zone 100 feet below the aquifer to provide a margin of safety. This would be consistent with existing state regulations, which require casing of all oil wells from the land surface to a depth 100 feet below the artesian aquifer.

The historic use of this criteria in State regulations indicates that administrative difficulties would be minimal. Moreover, data are adequate to present the boundary in map form (Figure 14). However, the artesian aquifer does not extend east of the Pecos River; a different approach is needed to provide aquifer protection in that part of the study area.

Alternative 4: Combination of Designation Techniques

To provide protection for fresh-water in the artesian basin as well as protection for those scattered sources outside the basin boundaries, a combination of designation techniques is necessary. A boundary placed 100 feet below the base of the artesian aquifer is feasible in the map area west of the Pecos River (Alternative 3). However, east of the river where the artesian aquifer does not occur, designation of boundaries would require careful scrutiny of well records and available geological data to determine zones productive of fresh water (using the procedures described in Alternative 2). The boundary drawn east of the river in Figure 14 is extrapolated from elsewhere in the area, and would need to be fixed in more detail if a UIC application were to occur east of the Pecos. This combination of options provides the best strategy for designating all potential sources of fresh water in the prototype area.

Figure 15 is a cross-section which identifies the boundary of the designated aquifer drawn according to Alternative 4. While this approach would require different types of administration in different parts of the prototype area, it also provides the most comprehensive protection. The administrative burden would not be significantly greater than that required for each individual technique above.

SUMMARY AND CONCLUSIONS

The prototype study has determined that boundaries can be set and aquifers identified under the UIC program. In the study area, existing state regulations can be used in coordination with UIC goals to carry out aquifer designations for the area west of the Pecos River. Designation of aquifers east of the Pecos requires use of geophysical data and available well records to determine appropriate boundaries based on total dissolved solids concentrations. This experiment provides many insights on the procedures to be used for UIC aquifer evaluations.

Geophysical data from oil and gas wells will be an important source of information, since they reveal conditions

in deeper aquifers, which, while not currently use for drinking water, should be protected under UIC. The TDS boundary method (Alternative 2) will be very useful in those areas which lack the geologically defined aquifer limit which occurs in the study area. The TDS method is likely to be used in much of New Mexico; however, the boundaries set will be less reliable than those established on a geologic basis, unless salinity is geologically controlled. A major administrative concern is that the procedures used in designating aquifers not change every time new data become available. This concern makes the exemptions of aquifers for hydrocarbon production an undesirable alternative.

The prototype study cost approximately \$100 per square mile. This provides a basis for budget estimates for other mapping elsewhere in New Mexico. Less cost and time will be involved in mapping the remainder of the Roswell basin as a result of the experience and techniques developed in the prototype area. Costs elsewhere in the state will vary depending upon data availability and the complexity of geologic and hydrologic conditions. Since most of the state will have little or no data available from deep wells, costs will be lower (and results less reliable) than in the prototype area.

The estimated cost of aquifer designation in New Mexico, based on \$100 per square mile, would be \$12,166,000. Even if costs eventually approach \$10/square mile, a considerable expense will be incurred by the UIC program. Where feasible, existing administrative procedures, such as New Mexico's state regulations, would reduce UIC costs considerably.

Table 4. Lithologic descriptions of units identified in Figure 2.

1. Alluvial Fill - unconsolidated sands, silts, and gravels.
2. Yates Formation - gypsum with minor dolomite and siltstone.
3. Seven Rivers Formation - anhydrite with shale, dolomite, and sandstone.
4. Queen Formation - sandstones with some sandy dolomite
5. Grayburg Formation - porous sandstone and sandy dolomite.
6. San Andres Formation - limestone and dolomite, with a more sandy and porous upper portion. The lower portion, or Slaughter Zone, has several anhydrite horizons and irregular high porosity development; the area between the upper zone and Slaughter lacks good porosity development.
7. Glorieta Sandstone Member - sandstone and siltstone with calcareous cement.
8. Yeso Formation - dark gray shales with carbonate-cemented siltstones, limestones, and anhydrite.
