1.0 Executive Summary

Geoscience Consultants, Ltd. (GCL) conducted a remedial investigation at the Brickland Refinery site in June and July 1994. The site is in Sunland Park, New Mexico and consists of 35 acres located along the Rio Grande. The former petroleum refinery operated from 1933 to 1958 and was subsequently dismantled. The primary objectives of the investigation included characterization of the nature and extent of hydrocarbons in the unsaturated zone and the physical, chemical, and biological properties of those soils. A secondary objective was to refine the understanding of geologic and hydrogeologic characteristics and their relation to groundwater flow and potential hydrocarbon migration. Quarterly groundwater monitoring samples and water level measurements were collected concurrent with the soils investigation.

The investigation included installation of 28 soil borings. 6 test trenches, and 4 additional groundwater monitoring wells. One hundred seventeen soil samples were collected for analysis to define soil properties considered critical for evaluating potential remedial action alternatives.

Results of the investigation indicate that refinery-related releases have occurred in the central to southern portions of the facility. Hydrocarbons in soil appear to correlate with concentrations observed in groundwater monitoring wells although the extent of free-phase hydrocarbons is very limited. Concentrations of total hydrocarbon constituents in soils ranged as high as 219 ppm and 290 ppm for the BTEX and PAH compounds respectively. Concentrations of these same compounds in groundwater ranged as high as 23 ppm for BTEX and 570 ppb for PAHs. A number of metals were detected at varying concentrations at locations across the site although the major metals of concern do not appear to have migrated into groundwater from the overlying soils.

Analytical results also indicate that significant quantities of clays and silts occur in heterogeneous and interbedded layers. These clays and their associated adsorptive properties serve to inhibit contaminant migration, slowing the process by which contaminants can leach into groundwater. From a remedial design perspective, site conditions limit soil remediation options the best of which may be in situ biotreatment.

Hydrogeologic analysis reveals that the groundwater flow direction beneath the site varies as a function of the river stage in the adjacent Rio Grande. In general,

groundwater flows in a southerly direction with local flow directions to the southeast and southwest. The groundwater flow direction will continue to be evaluated on a quarterly basis until sufficient data are available to determine how seasonal variations may impact any hydrocarbon migration and the effectiveness of any subsequent remedial action if required.

2.0 Introduction and Objectives

Previous investigations at the Brickland site (Eder, 1990) focused on determining the nature and extent of refinery-related releases to subsurface soils and groundwater underlying the facility. Samples were collected for analysis of typical hydrocarbon compounds and a number of metal constituents. Little information was provided regarding the chemical, physical, or biological properties of site soils and what influence these factors might have on natural degradation or attenuation of the compounds of concern, and what remedial alternatives might be appropriate considering site conditions.

The investigation conducted in June and July 1994 was designed to characterize the soil properties that would permit a determination of current site conditions and how they relate to constituent migration. It also provided the data necessary to allow a preliminary evaluation of potential remedial alternatives. Secondary goals of the investigation included a further evaluation of impacts to groundwater beneath the site and a thorough geologic/hydrogeologic characterization. Specific goals and objectives are as follows.

Soils Characterization

Soil samples were collected from 20 locations in the central to southern portions of the site (Plate A). Locations were selected based on historical data regarding facility operations and process areas, and the results of previous investigations. Four locations were also selected as sites for installation of additional groundwater monitoring wells to expand coverage of the existing monitor well network.

Analytical parameters were selected to further refine the understanding of the nature and areal distributions of hydrocarbon and metal constituents in subsurface soils. Selected samples were also analyzed for a number of physical and biological parameters to evaluate the influence of soil on constituent migration and attenuation, and determine whether natural soil properties are favorable or limiting for potential remedial alternatives. The investigation examined those properties which might have some applications in developing in situ remedial options that would result in containment or treatment of the various constituents. This included an evaluation of the biodegradation potential of the underlying soils and factors that might influence the physical movement of compounds in the subsurface (i.e., adsorption, porosity, permeability).

Groundwater Characterization

A quarterly groundwater monitoring program was established in December 1993 to evaluate impacts to the shallow aquifer beneath the site and to determine the extent of potential free-phase floating hydrocarbon. The program includes collection of samples from on- and off-site monitoring wells for analysis of volatile, semi-volatile and inorganic constituents, and measurement of water levels and free-phase hydrocarbon thickness. Four additional monitoring wells were installed during the June and July 1994 investigation to supplement the existing network and provide additional data on the presence and movement of hydrocarbons and metals in the subsurface. This information will help determine where recoverable hydrocarbons exist and the feasibility of potential remedial alternatives.

Geologic and Hydrogeologic Characterization

Regional and local geologic and hydrogeologic conditions will influence the fate and transport of compounds in the subsurface soils and underlying aquifer. Detailed lithologic descriptions were prepared for each borehole and trench. This, in conjunction with data provided by selected geotechnical analyses allowed the design of a conceptual model of subsurface conditions across the site. The surface geologic survey was conducted to further define the local geology and evaluate potential effects of subsurface fate and transport.

3.0 Sampling Methods and Techniques

Data to supplement that presented in previous investigations was obtained through the installation and sampling of soil borings, test trenches, monitoring wells, and well points, as well as a surface geologic survey. All sample locations, with the exception of those used in the geologic survey, are identified in Plate A. A detailed description of the methodologies used during the investigation is contained in the Sampling, Analysis and Quality Assurance Plan (SAP) for Remedial Investigation at the Former Brickland Refinery (GCL, 1994a).

3.1 Soil Borings and Test Trenches

Samples were collected from twenty-eight soil borings and six test trenches to characterize soil properties at the site and to evaluate potential remedial design alternatives. Four of the borings were completed as groundwater monitoring wells.

Soil samples were collected using a hollow-stem auger and split spoon samplers equipped with 2-foot Lexan tubes. All samples were collected, containerized, labeled, and shipped according to procedures outlined in the SAP. Total depth of the soil borings ranged from 8 to 12 feet, and cuttings were visually examined to allow preparation of detailed lithologic logs (Appendix A). Auger refusal conditions were not encountered during the investigation and all soil borings not completed as monitoring wells were plugged with bentonite and a non-shrinking grout. Soil cuttings were placed in labeled 55-gallon steel drums and field screened with a photoionization detector (PID) in order to segregate them into two sample groups that corresponded with highest and lowest PID measurements. One composite sample was taken from each group of the drummed cuttings for analysis by the Toxicity Characteristic Leaching Procedure (TCLP) for waste characterization and subsequent disposal, if necessary.

Six test trenches (Plate A) were excavated on June 22, 1994, to augment the samples collected from the soil borings and provide a better visual observation of the subsurface lithology. The trenches also proved useful in determining the distribution and movement of hydrocarbons beneath the site. The test trenches were excavated using a trackhoe and final dimensions were approximately 4 feet wide by 12 feet long by 8 feet deep. Spoils from the trenches were placed on plastic sheets and sampled for TCLP waste characterization.

3.2 Monitoring Well Installation and Development

Soil borings B-4, B-12, B-13, and B-14 (Plate A) were completed as monitoring wells to expand coverage of the existing groundwater monitoring network and to further evaluate the extent of floating free-phase hydrocarbons.

Each soil boring converted to a monitoring well was reamed to 12-inch diameter to accommodate the 4-inch monitoring well casing. The depth of the monitoring wells ranged from 24 feet at the central portion of the property to 31 feet at the south end. The monitoring wells were constructed using 4-inch diameter, flush joint, polyvinyl chloride (PVC) blank pipe; a 5-foot silt trap made of 4-inch diameter stainless steel; and 15 feet of 4-inch diameter, wire-wrapped stainless steel screen (0.01 to 0.02 inch slots). All casing was precleaned and prepackaged by the manufacturer.

The casing was lowered into the borehole through the hollow-stem auger, and auger flights were retrieved in 5-foot sections. A filter pack of precleaned and prepackaged 16-40 mesh silica sand was placed in the annulus around the screen as each auger flight was removed. The filter pack was installed to a level just above the top of the screen. Bentonite powder was then placed on top of the completed filter pack and hydrated with 5 gallons of distilled water to form an impervious barrier and prevent downward migration of fluids. The remainder of the annulus was grouted with a cement/bentonite slurry. Wells were completed with an above-grade protective steel pipe set in a 3-foot by 3-foot concrete well pad. Well locations and elevations were surveyed by a professional land surveyor. Monitoring well completion diagrams showing construction details, coordinates, and elevations are provided in Appendix B.

Monitoring wells were developed in one or two phases, depending on the amount of clay and silt that infiltrated the filter pack during completion. The first phase consisted of bailing water from the well to remove gross sediments. A jet pump with a 25-foot lift capacity was installed in the second phase. Water was pumped from several different screen intervals to facilitate well development. The wells were considered to be fully developed when indicator parameters of pH, temperature, and electrical conductance stabilized over three consecutive measurements. Parameters were allowed to vary ± 0.2 units for pH, ± 50 µmhos for conductivity, and ± 1°C for temperature.

3.3 Well Point Installation

Ten well points (Plate A) were installed to further evaluate the extent of free-phase floating hydrocarbons. The well points were constructed of 2-inch ID galvanized pipe with a 3-foot long screen (0.01 inch slots). The drilling rig was used to drive well points WP-28 and WP-29 into the soil. Well points WP-30 to WP-37 were installed in open boreholes. The screen intervals of 19 existing well points were adjusted to ensure contact with the desired aquifer interface. Well point completion diagrams are provided in Appendix C.

3.4 Geologic Survey

GCL personnel conducted a survey of the regional and local geology surrounding the Brickland site. This included reviews of existing geological publications, analysis and descriptions of local geologic units, and measurement of strikes and dips along local bedding planes and faults. Photographs of surficial geologic units were used for comparison with published geologic studies of the area. A full panoramic view of the geologic units bounding the western portion of the site is included in Appendix D.

4.0 Analytical Results

4.1 Soil Samples

During the investigation, 117 samples were collected to characterize the physical, chemical, and biologic properties of soil in the subsurface. Each borehole and trench was also visually logged to provide a full lithologic description. Results of the chemical, biological, and geotechnical analyses are provided in Appendix E.

4.1.1 Borehole/Trench Lithology

Three cross-sections (Plates B, C, and D) were constructed based on the presence and nature of the lithologic units encountered in the boring and trench investigations. These plates show the shallow lithology of the site in longitudinal and transverse views and incorporate data from earlier investigations. The cross-sections show interbedded units of clays, silts, and sands, and mixtures thereof, and are typical of the fluvial meandering stream environment of the Rio Grande. The underlying geology has influenced the movements of materials from the refinery and poses limitations on potential remedial alternatives due to their physical and chemical properties. Lithologic descriptions of all soil borings and test trenches are provided in Appendix A.

4.1.2 Chemical Samples

Seventy-seven samples were collected from the trenches and soil borings to further characterize the migration of materials from the surface to the subsurface. The number and location of soil samples collected for chemical analysis was based upon past refinery operations, previous investigations, and field observations and measurements. Hydrocarbon constituents are areally extensive in the central/southern portions of the facility and extend down to approximately 12 feet below ground surface making removal impractical.

Selected samples were analyzed for total petroleum hydrocarbons (TPH); benzene, toluene, ethylbenzene, and xylenes (BTEX); polynuclear aromatic hydrocarbons (PAHs); and RCRA metals. Sample locations and intervals are shown in Plates E through H. Analytical results are summarized in Tables 1 through 4 and the laboratory data are provided in Appendix E.

Total Petroleum Hydrocarbons (TPH)

Thirty-six samples were collected from locations across the site and analyzed by Environmental Protection Agency (EPA) Method 418.1 to determine the aggregate concentrations of aromatic, paraffinic, and olefinic compounds in soils. This method provides an indication of overall hydrocarbon content without specific compound identification. The soil sample results are shown in Table 1.

The highest TPH results (>1,000 mg/kg) were observed in samples collected in the central portion of the site and appear to coincide with former process areas. Samples from the southern half of the site also exhibited the presence of hydrocarbon, with a number of results exceeding 100 mg/kg. TPH compounds were present in samples ranging in depth from six inches to 12 feet below grade.

Benzene, Toluene, Ethylbenzene, and Xylenes (BTEX)

Ten samples were collected and analyzed by EPA Method 8020 for BTEX constituents. The soil sample results for BTEX are shown in Table 2.

Total BTEX concentrations exceeding 10,000 µg/kg were detected in soils near the central portion of the site and coincide with former process areas. BTEX was also detected in soils at the southern half of the site with total concentrations ranging from 6,900 to 769 µg/kg.

Polynuclear Aromatic Hydrocarbons (PAHs)

Ten soil samples were collected from various locations across the site for analysis of PAHs by EPA Method 8270; results of the sampling are shown in Table 3. These polycyclic compounds represent many of the heavier molecular weight hydrocarbons, and are semi-volatile in nature. As with the other hydrocarbon constituents, the highest concentrations of these compounds (>10,000 µg/kg) were found in soils in the central to southern portion of the site.

RCRA Metals

Sixteen soil samples were collected for total RCRA metals analysis. Metal parameters include arsenic, barium, cadmium, chromium, lead, mercury, selenium, and silver. Analytical results of the soil sampling are presented in Table 4. These analyses were conducted to complement data from earlier investigations, and to evaluate the potential impact of past refinery operations to soil and groundwater.

The metals analyses indicate that all of the metals are within the limits of naturally-occurring metals in soil, although lead, arsenic, and mercury are above the mean for these elements in soils in the western United States. Lead concentrations may be associated with historic operations at the site, however, some lead and arsenic found in site soils may be related to airborne deposition from the nearby Asarco smelter. The low levels of mercury detected in site soils may also be due to Asarco operations.

TCLP metal results indicate that lead is present in soils at one location above the TCLP (5.0 mg/L) limit. This soil sample obtained from a boring near the east-central portion of the site contained 82 mg/L lead. All other samples had low lead concentrations ranging from below the detection limit to 0.07 mg/L.

4.1.3 Biological Samples

Four samples were collected to characterize the level of heterotrophic and hydrocarbon-utilizing bacteria in subsurface soils and determine the biodegradation potential for petroleum constituents found at the site. Thirty-five soil samples were collected for analysis of macro-nutrient, humic content, total organic carbon, soil pH, and soil moisture content. Samples were collected from areas suspected of having the most significant levels of hydrocarbon content. Laboratory data for the bacterial analyses are provided in Appendix E and the summarized results are shown in Table 5 and Plate I.

Bacterial Classification

Heterotrophic and hydrocarbon-utilizing bacterial counts were conducted on four samples collected across the site to determine the potential capacity of indigenous microorganisms to degrade petroleum hydrocarbons in soil. The analyses evaluated those bacteria capable of degrading gasoline (i.e., volatile hydrocarbons) and fuel oil (i.e., non-volatile hydrocarbons), as well as the total number of organic carbon utilizing bacteria (i.e., heterotrophs). The results indicate that large bacterial populations (> 30,000 colonies/gm of soil) occur in soils where hydrocarbon concentrations are minimal. Bacterial counts decline significantly in soils with greater hydrocarbon content.

(4) Analysis by Hach Field Kit

G:\REXWORK\BIOSAMP.WQ1

Macro-Nutrients

Nitrogen (as nitrate or ammonia) and phosphorus (as ortho-phosphate) are essential compounds in bacterial nutrition and are often limiting factors for sustained bacterial growth and biodegradation. Four soil samples were collected and analyzed for these nutrients using a Hach field kit. Analytical results (Table 5) indicate that nitrogen and phosphorus are generally present in insufficient levels to promote widespread metabolism of indigenous bacteria. Optimal levels for nitrogen and phosphorus tend to average about 12.4% and 2.5% by weight respectively. However, preferred levels for both nutrients should be determined by a biotreatability study.

Humic Content

Three samples were collected for analysis of humic content by ASTM Method D-2974. This method determines biological debris that consists of dead bacteria and undigested substrate and is an indicator of potential metabolic activity. Humic content values varied from 1.0 percent to 2.7 percent and indicate that humic content in site soils is low and overall metabolic activity minimal.

Total Organic Carbon

Four samples were collected for analysis of total organic carbon by EPA Method 9060. Organic carbon serves as the primary energy source for bacterial metabolism. It also indicates the potential for bacterial survival in soil environments without additional carbon amendments. Organic carbon content in site soils ranged from 0.32 percent to 2.01 percent and indicates very little organic carbon in site soils. The optimal levels of organic carbon should be determined by a biotreatability study including its desired ratio to other nutrients.

pH

pH is an environmental factor that can limit and control the rate and magnitude of bacterial metabolism. A pH between 6 to 8 has been demonstrated to be optimal for bacterial growth rates. Five samples were collected for pH analysis by EPA Method 9045. Results ranged from pH 7.75 to 9.05 indicating a potential, although not optimal, environment for microbial growth.

Moisture Content

Soil moisture content can also limit bacterial growth. Soil moisture contents of 10 percent to 20 percent are preferable for optimum growth. Eleven samples were collected for soil moisture content determination by ASTM Method D-2216. Soil moisture contents range from 4.8 percent to 43.4 percent with a mean of 27.3 percent. The variance in soil moisture values is attributed to sampling depths. Most samples were collected from four to eight feet below the ground surface and had moisture contents on the order of 30 percent. Soil moisture content over most of the site is believed to be near optimum for microbial growth.

4.1.4 Geotechnical Samples

Geotechnical samples were collected for analysis of particle size, clay type, cation exchange capacity, bulk density, and hydraulic conductivity. These physical properties can reduce and/or attenuate compound migration in the underlying soils due to their absorptive properties. They can also often limit the application of many in situ remedial technologies due to these same properties. Analytical data for particle size distributions, clay type, and capillary moisture relationships are found in Appendix E.

Laser Particle Size Analysis (LPSA)

LPSA determines grain size distributions utilizing laser diffraction techniques. Dispersion patterns of a soil sample suspended in a liquid medium are recorded and analyzed by computer after being passed repeatedly through a laser beam. Particle size fractions are then reported as a percentage of the total sample volume.

Particle size distributions can be used to estimate soil permeability, which in conjunction with chemical vapor pressures, gives an indication of the feasibility of soil-vapor extraction (SVE). In general, SVE can be utilized when air permeabilities in soils are greater than 10 darcies, and chemical pressures are greater than 0.001 atmospheres (atm). Results from LPSA analyses and permeability estimates are shown in Table 6. As indicated by the permeability estimates for soils below the 0 to 4 foot interval (0.014 to 4.07 darcies) and listed vapor pressures for common hydrocarbon constituents (Table 7), SVE does not appear to be a favorable option, due to low soil permeability and the low vapor pressures of the majority of chemical compounds of concern. The interbedded

Table 6

Naphthalene	0.001
Phenanthrene	2.763×10^{-7}
Pyrene	3.289×10^{-9}

nature of the fine-grained soils beneath the site are also not conducive to SVE technologies.

Clay Type

Clays in the natural environment can play an important role in constituent migration since they have the capacity to adsorb metal ions and some organic compounds. Adsorption of metal species can occur through replacement of metals in the clay matrix (Al, Si) by available metal ions of similar size. Hydrocarbon molecules can adsorb to negatively charged clay particles as a result of induced polarization and the formation of carbonium ions (C^+). The degree of metal replacement and hydrocarbon bonding is a function of clay type and corresponding cation exchange capacity and surface charge.

Samples for clay type analysis were cleaned, desegregated, and split into clay-size and sand-silt size fractions. The clay fraction was analyzed by X-ray diffraction for quantitative clay typing based on reflection geometry. Four primary clays were identified by the X-ray diffraction analysis. These include illite, kaolinite, chlorite, and smectite. Illite, smectite and illite/smectite clay mixtures predominate in the samples and comprise 33 percent to 84 percent of the total content of the four clay types found in the samples. Clay type analyses are presented in Appendix E.

As indicated in Table 8, illite and smectite typically exhibit relatively high surface areas and net surface charges, as well as high cation exchange capacity (CEC). These properties can serve to reduce the migration of constituents at the site due to absorption of hydrocarbons and metallic species.

Cation Exchange Capacity (CEC)

CEC analyses were conducted using an adsorbed water method that relies on an empirical relationship of the moisture content ratio (by weight) of samples dehydrated by different methods to determine cation exchange capacity. CEC is most commonly reported in milliequivalents (meq of cations per 100 grams of soil (meq/100 gm) and represents the mass of any ion that can combine with or replace hydrogen in chemical reactions. CECs range from near 0 in sands to 100 meq/100 gm or more in certain clays. CEC affects the movement and retention of ions in the soil, which can be critical in processes involving the transport of organic and inorganic contaminants.

Table 8

Properties Related to Adsorption Characteristics of Clay

	Smectite	Illite	Kaolinite	Chlorite
Surface Area (m^2/g)	800	80	15	80
Surface Charge (meq/m^2)	1400	2875	1975	~2800
CEC (meq/100 g)	96	34	3	25

The three samples collected for CEC analysis had the following results: 12.4, 13.6, and 53.0 meq/100g (Table 9). The results indicate that the site soils have a moderate to high ion retention capacity.

Hydraulic Conductivity

Two samples were collected from the saturated zone of soil borings (B-04 and B-13) for constant head, vertical, and horizontal conductivity analysis by ASTM Method D-2434. The results of the two analyses are summarized in Table 9 and indicate a wide variability in hydraulic conductivities in lithologic units encountered across the site.

The sample from borehole B-04, a well-graded sand, had a relatively high vertical (19.2 cm/day) and horizontal hydraulic conductivity (19.7 cm/day). The sample from B-13, a poorly-graded silt, had very low conductivities; 0.0032 cm/day for vertical conductivity and 0.00306 cm/day for horizontal conductivity.

Dry Bulk Density

Two samples were collected from shallow soils for analysis of dry bulk density using API Method RP-40. Results from the two samples were very similar with densities ranging from 89.1 to 92.4 lb/ft^3 (Table 9). The soils are of the OL group, which consists of organic silts and silt-clays having low plasticities.

Capillary Moisture Relationship

Three soil samples were analyzed for capillary moisture relationship by ASTM Method D-2325 to define the hydraulic response expected from the soil types found at the site. Samples were collected from a silt, silty-sand, and sandy zone representative of the soil types at the site. As expected, water retention capacities varied with silt/sand ratios and the capillary moisture curves shown in Appendix E can be used to estimate unsaturated hydraulic conductivities that can be useful in predicting infiltration from seasonal precipitation, modeling aquifer responses to transient conditions, and estimating maximum loading rates for infiltration gallery designs.

4.1.5 Interpretation of Soil Sampling Results

Results from chemical analyses indicate that soils in the central to southern area of the site have been impacted by hydrocarbons and possibly metals (Plate N).

Lithologic descriptions and clay and particle size analysis results indicate that clays are present in sufficient quantities and in a heterogeneous and interbedded manner to effect the fate and transport of any of the constituents identified. These same site conditions also have the potential to limit the effectiveness of many remedial technologies that involve the use of mass transfer to remove constituents from the soil matrix to a carrier fluid such as air and water. If remedial action is determined to be necessary for soils, technologies involving biotreatment should be considered.

Other potential technologies include soil washing, solidification, and landfarming. These technologies are typically very intensive, however, and one potential difficulty is that significant dewatering might be required under high water table conditions.

Additional data collected indicates that biotreatment has potential, however, the existing environment would have to be modified to promote optimal metabolic growth.

4.2 Groundwater Samples

Water level measurements and samples for quarterly groundwater monitoring analyses were obtained during the remedial investigation. Interpretations of the hydraulic gradient and potentiometric surface based on the September 1994 water level measurements are presented in Section 4.3.1. The results of the chemical analysis follow below.

4.2.1 Chemical Samples

Seventeen existing and newly installed monitoring wells were sampled for the following parameters: WQCC metals, major cations and anions, polynuclear aromatic hydrocarbons (PAHs), phenols, and benzene/toluene/ethylbenzene/xylene (BTEX). Temperature, pH, and conductivity parameters were monitored during purging until measurements stabilized to ensure that representative groundwater

samples were obtained. A more detailed discussion of the quarterly sampling results will be presented in an annual sampling report.

Seventeen wells are included in the quarterly groundwater monitoring program at the Brickland site. These are:

• MW-1	• MW-2	• MW-3S and MW-3D
• MW-4	• MW-5	• MW-6S and MW-6D
• MW-7	• MW-8	• MW-9S
• MW-11	• MW-12	• MW-14
• MW-15	• MW-16	• MW-17

Three existing monitoring wells are excluded from the quarterly sampling and analysis program. Well MW-13 is not sampled since construction details of this well are unknown. However, this well is checked for water level and presence of product. Well MW-9D is no longer sampled due to casing failure; this well is filled with sediment. Well MW-10 is not included for sampling and analysis due to the presence of a thick layer of floating hydrocarbon; this well is checked for water level and product thickness.

Polynuclear Aromatic Hydrocarbons (PAHs)

PAHs were detected in four monitoring wells located in the central and southern portion of the site. Analytical results for PAHs are shown in Table 10. Well MW-5 had reported concentrations of 1-methylnaphthalene, 2-methylnaphthalene, and naphthalene at 78, 12, and 27 µg/L, respectively. The sample from well MW-8 had a reported value of naphthalene at 93 µg/L. The nearby well MW-14 exhibited concentrations of 1-methylnaphthalene, 2-methylnaphthalene, and naphthalene at 160, 180, and 230 µg/L, respectively; MW-14 contained the highest level of the detected PAHs at the site. Well MW-15, near the southern boundary of the site, had reported values of 1-methylnaphthalene, 2-methylnaphthalene, and naphthalene at 61, 41, and 15 µg/L, respectively. PAHs were not detected in any other well.

Phenols

Phenols were detected in two wells near the central portion of the site. Analytical results for phenols are shown in Table 11. Well MW-8 had 2,4-dimethylphenol

and phenol values at 56 and 110 µg/L, respectively, and MW-14 had a phenol concentration of 300 µg/L.

WQCC Metals

Third quarter groundwater sampling results indicate that many WQCC metals are not present at levels above the detection limit or are present at insignificant levels. As shown in Table 12, the metals not found above the detection limit include: chromium, cobalt, lead, mercury, molybdenum, and selenium.

Cadmium and silver were present at very low levels near the southerly portion of the property. One well contained cadmium at 0.009 mg/L, and two wells contained silver at 0.01 mg/L. Neither appear to be a result of facility operations.

Copper and zinc were detected at low levels across the site in no discernable pattern. Copper was detected in four wells at 0.01 mg/L, and zinc was detected in five wells and ranged from 0.01 to 0.09 mg/L.

Arsenic was detected in four wells near the southern portion of the property; arsenic values ranged from 0.05 to 0.08 mg/L.

Aluminum was detected in 10 wells, located along the bank of the Rio Grande and in the southern portion of the site. Aluminum values in groundwater ranged from 0.05 to 2.32 mg/L.

Barium, manganese, and iron are ubiquitous in the groundwater wells at the site. Barium values range from 0.02 to 1.24 mg/L; manganese from 0.01 to 7.47 mg/L; and iron from 0.06 to 5.79 mg/L. The distribution of these metals in groundwater across the site do not present a distinctive pattern.

Major Anions and Cations

Summarized analytical results for bicarbonate (HCO^{3-}), chloride (Cl^{-}), nitrate (NO^{3-}), and sulfate (SO_4^{2-}), calcium, magnesium, potassium, and sodium are shown in Table 13.

Bicarbonate values at the site range from 473 to 2,670 mg/L, and generally increase from the Rio Grande toward the interior of the site. Chloride values range from 39.3 to 7,200 mg/L, but do not show a consistent spatial pattern across the site.

3031/RPTANC.WQ2

Nitrate was not detected in three site wells. Concentrations in all other wells ranged from 0.1 to 10 mg/L. The highest nitrate value, 10 mg/L, is from MW-6D, adjacent to the Rio Grande. The next highest nitrate value, 2.8 mg/L, is from MW-4, in the central portion of the site. There is no discernable or consistent spatial pattern of nitrate occurrence across the site.

Sulfate values range from 18 to 2,790 mg/L in groundwater at the site. While there is no distinctive pattern for this anion, wells along the Rio Grande appear to show the highest values of sulfate, particularly the deeper wells.

Calcium concentrations ranged from 57.7 to 1,080 mg/L across the site, and are generally highest in upgradient wells and those closest to the Rio Grande. Magnesium concentrations ranged from 15.4 to 500 mg/L and show the same general trend as calcium. Potassium and sodium concentrations ranged from 11.4 to 125 mg/L and 105 to 3,300 mg/L, respectively, and show trends similar to calcium and magnesium.

BTEX

Analytical results for BTEX compounds in groundwater are summarized in Table 14. Benzene was detected in groundwater samples from 11 of the 17 monitoring wells. Values ranged from 0.6 µg/L to 23,000 µg/L in groundwater. Very low to intermediate concentrations (0.6 to 110 µg/L) were detected in wells along the Rio Grande and near the southern portion of the facility. The highest values of benzene (1,800 to 23,000 µg/L) were located in the central portion of the property.

Toluene was only detected in one monitoring well near the central portion of the site; the reported value was 12 µg/L. Ethylbenzene was reported in four wells, two located near the Rio Grande and two within the central and southern portion of the property. Ethylbenzene values in these wells ranged from 13 to 50 µg/L. Xylene was detected in the wells in the central and southern portions of the property and in two wells along the Rio Grande. Concentrations ranged from 0.6 µg/L to 130 µg/L.

4.2.2 Interpretation of Groundwater Sampling Results

The results of the quarterly groundwater sampling conducted during the remedial investigation augment the results of the soil sampling investigation and provide

3031/RPTT

insight into the distribution of background levels of naturally occurring compounds vs. those indicated to be associated with the site activities.

The concentrations and distributions of WQCC metals and major anions/cations found in on- and off-site monitoring wells indicate that existing concentrations in soil have not been a source for the constituents detected in groundwater underlying the site. The levels of barium, iron, and manganese found in groundwater at the site are similar to those reported from shallow aquifers at other locations along the Rio Grande. Similarly, major cations and anions are highest in groundwater wells located upgradient and along the bank of the Rio Grande. The chemistry of the shallow groundwater at the Brickland site indicates that the water is saline and sulfate-rich, and not a potable groundwater source. The chemistry also indicates that the brackish water has a high scaling potential.

The presence and location of BTEX compounds, PAHs, and phenols in the groundwater coincide very well with areas of known hydrocarbon occurrences in soil, although it appears that there may be low-level sources of benzene upgradient of the site. Groundwater impacts associated with historic site operations are concentrated in the areas of the old refinery near the west-central portion of the facility and the pond area near the southern boundary of the site. Soils at these locations are continuing sources of hydrocarbon constituents. Monitoring wells within these areas show elevated concentrations of benzene, phenol, 1-methylnapthalene, and naphthalene. It is also apparent that benzene has migrated from the site at and near the location of MW-6S.

4.3 Geology and Hydrology

4.3.1 Regional Geology and Hydrology

The Brickland Refinery site is located within the southern part of the Mesilla Basin and Range Province and is situated on the western flood plain of the Rio Grande, between the southern tip of the Franklin Mountains and Cerro de la Cruz (Cerro de Muleros).

Geologic structures in the area are a result of deformations associated with the Tertiary andesitic and felsic Cristo Rey uplift. On the east side of the uplift, adjacent to the river, a series of southeast to northwest trending structural features are present. They have been identified from west to east as the Aqueduct anticline, the Power Line syncline, and the Brick Plant anticline (Lovejoy 1976).

The Brickland site is located at the approximate crest of the Brick Plant anticline. Several southeast to northwest trending normal faults (up to the east) are also present associated with the folding. The surface expression of these faults can be seen in the Cretaceous outcrop just beyond the southeastern edge of the Brickland property. At least one of the major faults is believed to extend across the southern end of the site.

The rocks exposed at the surface are relatively recent (Holocene) alluvial deposits of the Rio Grande. The alluvium extends along the river flood plain and covers much of the Cretaceous deformation and faulting at the site. Below the alluvium, to the north, east, and south of the site is the Quaternary/Tertiary Santa Fe Group (bolson deposits) also known as the Fort Hancock Formation. The bolson sediments rest unconformably above the Cretaceous rocks and are composed of alternating lenticular beds of sand, clay, and gravel. The bolson deposits are not present below the Brickland site where the Rio Grande Alluvium is underlain by erosionally breached, Lower Cretaceous rocks.

Groundwater in the region is supplied by three major sources: (1) the Hueco bolson deposits (Santa Fe Group - Lower El Paso Valley), (2) the Mesilla bolson deposits (Santa Fe Group - Upper El Paso Valley), and (3) the Rio Grande Alluvium. A portion of the water supply for the city of El Paso is also taken from the surfacewaters of the Rio Grande. The supply intake is located in the American Canal approximately 4 miles downstream of the Brickland site.

The Hueco bolson aquifer is located primarily on the east side of the Franklin Mountains and along the Rio Grande to the southeast. It is not present near the Brickland Refinery site, but is hydrologically connected to both the Mesilla bolson and the Rio Grande Alluvium (Alvarez & Buckner 1980).

The Mesilla bolson aquifer is present in several wells located across the river from the Brickland site. This aquifer is a thick section of older alluvium (up to 2,000 feet in thickness) that extends approximately two miles east of the river, up the slope of the Franklin Mountains. North from Cerro de Cristo Rey, the formation spreads to the west as valley fill for the Mesilla basin. Use of the Mesilla aquifer near the site is minimal.

The Rio Grande Alluvium aquifer is approximately 80 feet thick (Richardson, 1909) and is confined near the site to the present river flood plain. In most places, the recent alluvium has been deposited above the Mesilla and Hueco bolson. It is hydrologically connected with the underlying aquifers and the Rio Grande.

4.3.2 Local Geology and Hydrology

The shallow geology at the site is composed of Quaternary (Holocene) alluvium deposited by the Rio Grande. It consists of clay, silt, sand, and gravel that ranges from thin-bedded heterogeneous lenses to massive homogeneous units. The sediments encountered during the soil boring and trenching operations can best be described in two general categories: the shallow, thin-bedded heterogeneous clastics, and the deeper more homogeneous sands.

The base of the shallow unit has been identified by a somewhat consistent, pale brown, silty clay at approximately 7 to 9 feet below the surface (11 to 14 feet on the southern end of the site). The shallow unit consists of thin-bedded, fine-grained sand, silt, and silty clays that can rarely be correlated over a distance greater than 150 to 200 feet. The sediments were likely deposited by flood stage waters from the adjacent river. On the south end of the property, the upper portion of the shallow unit has apparently been removed either by erosion or the excavation of the former Brickland refinery waste ponds. The shallow soil in this area presently consists of a yellowish-brown, fine- to medium-grained sand believed to have been dredged from the river to back-fill the ponds. A remnant of the silty clay base of the shallow unit is present at approximately 8 to 11 feet in borings B-12 and B-13. The aquifer encountered in this shallow unit is partially confined to the sandier members, with the clay layers acting as aquitards.

Below the deepest silty clay is a massive, homogeneous, gray to yellow-brown, fine-grained sand characterized by well-sorted, subrounded sand grains that appear to coarsen with depth. Monitoring well drilling logs from previous investigations in some of the deeper wells. The aquifer in the deeper unit appears to be partially confined by the overlying silty clay, and appears hydraulically connected to the shallow aquifer at various locations across the property. Both the deep and shallow aquifers are strongly influenced by the hydrology of the Rio Grande.

Plate J was prepared with the water level obtained data from the site monitoring wells. The map indicates the hydraulic gradient under the assumption that both the shallow and deeper lithologic units are hydrologically connected.

5.0 Conclusions

The results of the investigation provide an estimate of the vertical and horizontal distribution of petroleum hydrocarbons at the former Brickland refinery site. Plates K, L, and M show the transverse and horizontal extent of subsurface petroleum constituents, based upon the results of this and previous investigations. Plate N shows the areal extent of petroleum contamination, based upon this information; soil TPH values within this area generally exceed 100 mg/kg.

The hydrocarbons contained in site soils have impacted underlying groundwater, and provide a continuing source via this pathway. The fluctuation of the shallow groundwater beneath the site has produced a "smear zone" in which the more mobile petroleum hydrocarbons have been transported vertically and horizontally through site soils.

Sampling results indicate that lead is the only site-related metal of concern in soil. At one location, lead values in soil exceed TCLP limits, however, lead has not been detected in any groundwater monitoring well to date. No other metals of concern have been noted in either soil or groundwater.

Biological and geotechnical parameters at the site indicate that naturally occurring biodegradation processes may be augmented within the site soils. Clay types and cation-exchange capacities suggest that contaminants are being adsorbed onto site soils, and are only slowly being released to groundwater.

Based on water levels collected by GCL, both the shallow and deep lithologic units are in direct communication with the Rio Grande. In July 1994, when monitoring wells were measured, the river was flowing at a capacity approaching flood stage. As a result, the potentiometric contour map reflects a condition where the river is losing, and therefore, recharging the aquifer as demonstrated by the decrease in potentiometric contours away from the river bank. Groundwater flow direction is primarily toward the south end of the site with a hydraulic gradient of about 0.0016 (ft./ft.).

On the basis of the local geologic and hydrologic data, the shallow flood plain aquifer at the Brickland site appears to be in communication with the river. The sandy sediments that make up the aquifer are bounded to the north and east by the recharging barrier of the Rio Grande and to the west and south by Cretaceous bedrock (Lovejoy, 1976).

Based on the September 1994 potentiometric contour map, the shallow aquifer beneath the site discharges to the south and southeast as throughflow. Additional discharge through fractured Cretaceous bedrock located below the flood plain sediments cannot be ruled out, but is expected to be small relative to throughflow. As noted earlier, the system of southeast to northwest trending normal faults, related to the Cristo Rey Uplift, were identified from surface geologic mapping and available literature (Lovejoy, 1976). Groundwater from the deeper homogeneous sediments may also be discharging into the fracture system, causing several localized areas of natural potentiometric surface depressions.

6.0 Recommendations

GCL recommends that groundwater beneath the site continue to be monitored for an additional two consecutive quarters prior to initiation or selection of any remedial action. This monitoring should consist of sampling the current network of 17 monitoring wells, and analyzing those samples on a quarterly basis for BTEX, TPH, PAH(s), phenolic compounds, and WQCC metals. In addition, groundwater monitoring should include collection of groundwater level data from all 20 monitoring wells and 37 well points associated with the site. This monitoring will verify and document suspected seasonal variations in contaminant trends and groundwater movement patterns. This information will also aid in the design of any remedial system that has to account for these seasonal variations.

At this point there does not appear to be a significant risk to potential receptors via a groundwater or surfacewater pathway. However, if after two consecutive quarters, it is verified that contaminated groundwater from the site impacts the only known potential receptor pathway (i.e., the Rio Grande) a Remedial Action Plan will be prepared and submitted to the New Mexico Oil Conservation Division. The plan will provide recommendations to mitigate any potential threats to human health or the environment from the Brickland site.

Although remedial actions are not anticipated, such actions might include containment of contaminated groundwater on site by a pump-and-treat system, and the cut-off and/or treatment of known and suspected source areas. The source areas are suspected to be localized areas of free-phase floating product and petroleum-contaminated soil zones that are hydraulically permeable and exhibit leaching characteristics. To date, metals in groundwater do not appear to pose any serious problems. Implementation of any remedial actions would take a phased approach to integrate the understanding of site characteristics with assessments of potential risks and provide a cost-effective remedy. The effectiveness of a phased approach can be assured by including provisions for ongoing monitoring at the Brickland site.

FINAL REPORT PRESENTED
JULY 13, 1994

INTRODUCTION

Core Laboratories was requested to perform a soil analysis study on behalf of Geoscience Consultants, Ltd. on core samples recovered from the Rexene Project. Presented herein are the results of this study.

The report is divided into six sections. The first section, Analysis Request Summary, identifies the requested procedures and tests for each sample. Also included in the first section, Analysis Techniques, which gives a description of analysis. The second, Geotechnical Analysis Results, contains a tabular presentation of the soil analysis data. The third section, Clay Typing Analysis by X-ray Diffraction, is presented in tabular form. The forth section, Laser Particle Size Analysis, is presented graphically and in tabular form. The fifth section, Capillary Moisture Relationship, is also presented graphically and in tabular form. The last section contains copies of the chain of custodies for the Rexene Project.

We appreciate this opportunity to be of service and hope these data prove beneficial in the development of this project.

Analysis Techniques

Bulk Density, Particle Size Distribution, Hydraulic Conductivity, Moisture Content, Humic Content, Capillary Moisture Relationship, Cation Exchange Capacity, X-Ray Diffraction

The samples were analyzed utilizing techniques described in API RP-40 (Bulk Density), ASTM D-2216 (Moisture Content), ASTM D-2434 (Hydraulic Conductivity), ASTM D-2974 (Organic Content), and ASTM D-2325 (Capillary Moisture Relationship). Techniques for X-ray Diffraction and Laser Particle Size Analysis are also described below.

Sample Preparation (Bulk Density)

A one-inch diameter plug was drilled from each submitted sample. Liquid nitrogen was used as the bit coolant.

Bulk Density Determination (API RP-40)

One inch diameter plugs were taken from each submitted sample. Bulk density was determined upon each plug as described in API RP-40.

The bulk volume of each sample was calculated using Equation 1.

$$V_b = V_p + V_g \quad (1)$$

Where: V_b = Bulk Volume
V_p = Pore Volume
V_g = Grain Volume

Bulk Density was calculated using Equation 2.

$$D_b = M_g / V_b \quad (2)$$

Where: D_b = Bulk Density
M_g = Dry Grain Mass
V_b = Bulk Volume

Laser Particle Size Analysis (LPSA)

LPSA determines the grain size distribution of a sample by utilizing laser diffraction techniques. A small portion of each disaggregated sample was

dispersed in a liquid medium and repeatedly passed through a laser beam. The resultant dispersion patterns were recorded and analyzed by computer. Particle size fractions are determined as a percentage of the total sample volume and are presented in tabular and graphic formats.

Hydraulic Conductivity Determination (ASTM D-2434)

The soil sample tubes were trimmed in length to fit into the hydraulic conductivity apparatus. The end surfaces were plane and perpendicular to the longitudinal axis of sample. 120 mesh screens were applied to top and bottom of the samples to reduce the possibility of sample movement during testing. The samples were undisturbed and tested in the state in which they were received. Once mounted in the conductivity system, the samples were vacuumed for one-half hour to remove any trapped air in the soil and apparatus. While under vacuum the samples were then saturated with water. A graduated burette was used to measure the initial and final hydraulic head and determine volumes of water introduced to the sample.

The samples were tested and measured a total of six times apiece. A five percent accuracy parameter was used to determine the validity of the experiments. The tests were consistent with the constant tailwater pressure method, Equation 3. Water flowed through the sample until constant flow condition was observed.

$$k = (a * L / A * t) * \ln(h_0/h_1) \qquad (3)$$

Where:

k = Permeability, meters/second

a = Cross-sectional area of the reservoir containing the influent liquid in meters^2

L = Length of sample, meters

A = Cross-sectional area of the sample, meters^2

t = Total time in seconds

h_0 = initial height of water column above chamber outflow port in meters

h_1 = final height of water column above chamber outflow port in meters

Moisture Content Determination (ASTM D-2216)

Upon receipt of the samples, material was removed from both ends of each tube submitted for moisture content determination, immediately weighed, placed into tared drying dishes, and then placed into a convection oven at 110° C until stable dry weights were attained. ASTM water content of the material was calculated using Equation 4.

$$w = [(W_1 - W_2)/(W_2 - W_c)] \times 100 = W_w/W_s \quad (4)$$

Where:

w = water content, %

W_1 = mass of container and moist specimen, g

W_2 = mass of container and oven-dried specimen, g

W_c = mass of container, g

W_w = mass of water, g

W_s = mass of solid particles, g

Humic/Organic Content Determination (ASTM D-2974)

Upon receipt of the samples, material was removed from both ends of each tube submitted for organic content determination, immediately weighed, placed into tared drying dishes, and then placed into a convection oven at 110° C until stable dry weights were attained. After recording the oven dried weight the sample was transfered to a furnace and ignited at 440° C. The substance remaining after ignition is the ash. The ash content is expressed as a percentage of the

mass of the oven-dried sample. The organic matter is determined by subracting percent ash content from one hundred. ASTM ash content of the material was calculated using Equation 5.

$$a = (c \times 100)/b \quad (5)$$

Where:

a = ash content, %

c = mass of ash, g

b = oven-dried specimen, g

ASTM organic content of the material was calculated using Equation 6.

$$om = 100.0 - a \quad (6)$$

Where:

om = organic matter, %

a = ash content, %

Capillary Moisture Relationship (ASTM D-2325)
Porous-Plate Method

The saturated soil samples are placed in contact with a saturated porous plate installed within a pressure chamber. The bottom of each plate is sealed to be airtight. The bottom of each plate is maintained at atmospheric pressure by means of a small drain tube. A desired air pressure (tension) is admitted to the pressure chamber. The volumetric water displaced is monitored until equilibrium. The moisture content of the sample is calculated using equation 7. The procedure is repeated for five additional tension points (between 0.1 and 1 atm).

$$\text{Moisture equivalent} = \text{Moisture Weight/Sample Dry Weight} \quad (7)$$

Cation Exchange Capacity Determination (Adsorbed Water Method)

A representative sample from each tube selected for CEC analysis was prepared for testing by cleaning, disaggration and air drying. The sample is then placed

in a relative humidity oven for seventy-two hours at RH 45% and 60° C. At the end of this time interval, the sample is cooled to room temperature and weighed to the nearest milligram.

The sample is then dried for twenty-four hours at 110°C in a convection oven. The sample is then cooled to room temperature and weighed to the nearest milligram. The Adsorbed Water Indicator (AWI) for the sample is calculated by equation 8.

The Cation Exchange Capacity, milliequivalents/100gm, of the sample is then determined empirically by utilizing a conversion chart developed by Core Laboratories Research and Development.

$$AWI = W_2/W_1 \qquad (8)$$

Where:

AWI = Adsorbed Water Indicator

W_1 = Weight of the humidified sample, g

W_2 = Weight of the oven-dried sample, g

X-ray Diffraction (XRD) Clay Typing

Representative samples were selected from the tubes submitted for XRD analysis. Samples were cleaned, gently disaggregated, and split into clay-size fraction and sand-silt size fraction. The clay size fraction was then analyzed for quantitative clay typing.

X-ray diffraction analysis is a method used for finding the mineral content of a substance. X-ray diffraction is based on the measurements of X-ray reflection geometry. The condition for reflection of X-rays from a parallel arrangement of atoms within a crystal is called the Bragg Angle. The fundamental measurement made with XRD is "d-spacing" of the mineral lattice determined by Bragg's Law, equation 9.

$$n\lambda=2d\sin\theta \qquad (9)$$

Where:

n = order of reflection

λ = wavelength of incident X-rays

d = interplanar spacing between rows of atoms

θ = angle of incident X-rays

Sample Disposition

The residual sample will be stored for thirty days at our Bakersfield facility pending instructions for additional work or permanent storage arrangements.

WESTERN ATLAS

Core Laboratories

SAMPLE DELIVERY GROUP NARRATIVE

August 15, 1994

Customer: Geoscience Consultants, Ltd.
Project: Rexene COC #8279
Core Laboratories Project Number: 941556

On 6-24-94 Core Laboratories received samples for analysis. The following information is pertinent to the interpretation of the data package.

Organic Analysis:

During the analysis for PAH semivolatiles, a matrix interference was present in sample ID 9406221050 which required a high sample dilution. Sample ID 9406221050 has a elevated detection limit because of the high dilution.

Project: Rexene COC # 8279
Core Laboratories Project Number: 941556

On 6-24-94 Core Laboratories received samples for analysis. The following information is pertinent to the interpretation of the data package.

Method 8020 GC Analysis :

The medium level extraction blank that was extracted with the 941556 samples was analyzed on 7-10-94.

The method blank analyzed with the 941556 samples had a hit for xylenes at 2 ug/kg. Sample 941556-3 (9406220942) also had a hit for xylenes. It is flagged with a "B".

Core Laboratories policy is to run CCV's after every ten samples. CCV's were run at the start and end of the daily run instead of every ten samples. Spike blank and spike blank duplicates were prepared in exactly the same way as the CCV's and analyzed after 12 samples. All of the QC was acceptable.

EXPLANATION OF DATA FLAGS

B - This flag is used to indicate that an analyte is present in the method blank as well as in the sample. It indicates that the user should consider this when evaluating the results.

D - This flag indicates that surrogates were diluted out of calibration range and cannot be quantified.

E - This data flag indicates that a sample result is an estimate because the concentration exceeded the calibration range of the instrument.

J - Indicates that a value is an estimate. It is used when a compound is determined to be present based on the mass spectral data, but at a concentration less than the practical quantitation limit of the method. This flag is also used when estimating the concentration of a tentatively identified compound.

X - This flag refers the client to an included case narrative for additional information which may be useful in data evaluation.

* - Used to indicate matrix interference.

SAMPLE DELIVERY GROUP NARRATIVE

August 15, 1994

Customer: Geoscience Consultants, Ltd.
Project: Rexene COC # 8284
Core Laboratories Project Number: 941557

On 6-24-94 Core Laboratories received samples for analysis. The following information is pertinent to the interpretation of the data package.

Method 8020 GC Analysis :

The medium level extraction blank that was extracted with the 941557 samples was analyzed on 7-10-94.

The method blank analyzed with the 941557 samples had a hit for xylenes at 2 ug/kg. Sample 941557-6 (9406221620) also had a hit for xylenes. It is flagged with a "B".

Core Laboratories policy is to run CCV's after every ten samples. CCV's were run at the start and end of the daily run instead of every ten samples. Spike blank and spike blank duplicates were prepared in exactly the same way as the CCV's and analyzed after 12 samples. All of the QC was acceptable.

Linda L. Benkers
QA/QC Coordinator

James H. Travis
Laboratory Supervisor

WESTERN ATLAS

Core Laboratories

EXPLANATION OF DATA FLAGS

B - This flag is used to indicate that an analyte is present in the method blank as well as in the sample. It indicates that the user should consider this when evaluating the results.

D - This flag indicates that surrogates were diluted out of calibration range and cannot be quantified.

E - This data flag indicates that a sample result is an estimate because the concentration exceeded the calibration range of the instrument.

J - Indicates that a value is an estimate. It is used when a compound is determined to be present based on the mass spectral data, but at a concentration less than the practical quantitatic limit of the method. This flag is also used when estimating the concentration of a tentatively identified compound.

X - This flag refers the client to an included case narrative for additional information which may be useful in data evaluation.

* - Used to indicate matrix interference.

SAMPLE DELIVERY GROUP NARRATIVE

August 3, 1994

Customer: Geoscience Consultants, Ltd.
Project: Rexene Project
Core Laboratories Project Number: 941540

On 6-22-94 Core Laboratories received samples for analysis. The following information is pertinent to the interpretation of the data package.

Organic Analysis:

During analysis of PAH semivolatiles on sample ID 9406201625, nitrobenzene surrogate was not recovered. Reanalysis of the sample confirmed the original result. It is believed that the high matrix interference present caused problems with detecting and quantitating the nitrobenzene surrogate.

The reported total petroleum hydrocarbon (TPH) analysis on sample ID 9406181050 Location B-9A was performed six days past the EPA recommended holding time. This error occurred at the time of sample login and receipt when sample ID's 9406181050 Locations B-9 and B-9A were logged in as a single sample. TPH analysis on sample ID 9406181050 Location B-9 was performed within holding time; however, TPH analysis was requested on the container labeled B-9A. Reanalysis using the correct sample was performed as soon as the error was detected.

Dear Mr. Thomas,

Enclosed please find the analytical results for the samples received by the Remediation Technology Laboratory on 6/22/94.

Analytical work for this project has undergone a rigorous Quality Assurance/Quality Control procedure to ensure quality and accuracy. Your reference number for correspondence regarding these results is R7013 and your contact person is George E. Hocker.

All samples will be discarded 8/20/94, unless directed otherwise. If you have any questions regarding this analysis, or if we can be of further assistance, please call us at (510) 671-2116.

Sincerely,
GROUNDWATER TECHNOLOGY, INC.

Results of Bacteria Enumeration

Project Name:	Rexene	**Sampling Date:**	6/17/94
Client Name:	GCL	**Date Received:**	6/22/94
Site Location:	Unknown	**Date Completed:**	7/18/94
Project Manager:	Trent Thomas	**Report Date:**	7/20/94
Matrix:	Soil	**Log-In Number:**	R7013

	Lab No.	Sample ID	Contaminant Utilizing Bacteria(1)		Total Heterotrophic Bacteria	
			Non-Volatile	Volatile		
B-1	7013-1	9406171043	3.1×10^4	3.7×10^4	2.6×10^5	4-6'
B-3	7013-2	9406171502	7.7×10^3	(8.2×10^2)	3.1×10^4	6-8'

(1) Contaminant = Non-Volatile-Fuel Oil
Volatile-Gasoline

Plate counts reported in colony-forming units per dry gram soil. Spread plate technique based on Methods of Soil Analysis, Part 2, Chemical and Microbiological Properties, Amer. Soc. of Agronomy, Soil Science Soc. of Amer., 1982, Madison, WI chapter 37; Standard Methods for the Examination of Water and Wastes, 17th edition, AWWA, APHA, WPCF, 1989, Method 9215C. Results in parentheses do not fall within the range of 30-300 colonies per plate and are therefore reported as estimated counts.
