## Development of Overpressure

## **Development of Normal Pressure**

Weight of overlying strata pushes down on uncompacted sediments.

- Sediments are surrounded by a permeable layer.
- 2.) Water is forced out of the sediments.
- 3.) Sediments compact until they are in grain-to-grain contact.

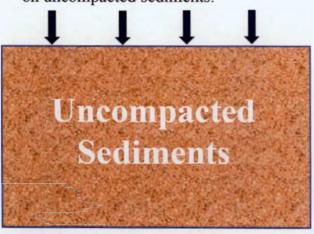

With deeper burial, the weight of overlying strata increases, but this weight is supported by the rock grains.

Pore pressure increases at hydrostatic gradient.

## **Development of Overpressure**

Weight of overlying strata pushes down on uncompacted sediments.

- 1.) Sediments are surrounded by an **impermeable** layer (e.g., shale, salt).
- 2.) Water cannot escape, and compaction cannot occur.
- 3.) Weight of overlying strata is supported by formation fluids in the undercompacted layer and not by the rock grains.
- 4.) This is like standing on a water-filled balloon.

  BEFORE THE OIL CONVERSATION

DIVISION
Santa Fe, New Mexico
Exhibit No. 30
Submitted by: OXY USA Inc.
Hearing Date: March 29, 2016

Undercompacted sediments

Weight of overlying strata is **supported** by formation fluids and not by the rock grains. Pore pressure increases at lithostatic gradient and this interval is **overpressured**.
